**ABSTRACT**

For many years, left main coronary artery disease has remained as the last frontier resisting percutaneous coronary intervention. Until recently, the most relevant clinical studies in this regard as well as clinical practice guidelines favored surgical revascularization almost as the only treatment pathway for the management of this condition. The changes that have occurred over the last 10 to 15 years since the appearance of drug-eluting stents and their technological advances have been extraordinary. This, added to the publication of randomized clinical trials that compared both revascularization modalities, has placed percutaneous coronary interventions at a similar level to surgery in a large number of patients. The anatomical, technical, and strategic aspects are essential for the percutaneous management of left main coronary artery lesions given their tremendous clinical variability. In this article we will be reviewing their anatomy, angiography, intracoronary diagnostic techniques, and different percutaneous revascularization strategies. As long as future clinical studies do not definitively favor percutaneous over surgical revascularization or vice versa, individual discussions on each particular case by the heart team and our patients' preferences should guide our clinical decision-making process.

**RESUMEN**

La enfermedad del tronco coronario izquierdo ha permanecido muchos años como la última frontera que se resistía al intervencionismo coronario percutáneo. Hasta hace poco tiempo, los estudios clínicos más relevantes en este campo, así como las guías clínicas, han sido favorables a la revascularización quirúrgica casi como forma exclusiva de tratamiento de esta patología. Los cambios ocurridos en los últimos 10-15 años, desde la aparición de los stents farmacoactivos y su mejora tecnológica, han sido vertiginosos. La realización de estudios aleatorizados que han comparado ambas modalidades de revascularización ha llevado al intervencionismo percutáneo a la altura de la cirugía en un alto porcentaje de pacientes. Los aspectos anatómicos, técnicos y de estrategia son fundamentales en el tratamiento percutáneo de estas lesiones, dada su enorme variabilidad clínica. En tanto los estudios clínicos futuros no se decanten definitivamente a favor de la revascularización percutánea o de la quirúrgica, la discusión individualizada de cada caso en un equipo multidisciplinario y las preferencias de los pacientes deberían guiar la decisión clínica.

INTRODUCTION

Significant left main coronary artery (LMCA) disease is present in 4% to 5% of all coronary angiographies. Since the LMCA supplies over 75% of all the myocardial blood flow, the risk associated with its lesions is the highest of all possible coronary lesions. Without revascularization, its prognosis is poor and mortality rate can be up to 37% at 3-year follow-up. Revascularization can be surgical or percutaneous, each one with its corresponding advantages and limitations. Assessing anatomic spread correctly, the complexity of coronary artery disease, the patient’s comorbidities, and the operator’s expertise in complex percutaneous coronary interventions (PCI) are key factors when choosing the right revascularization strategy. There are different models and scales to guide the selection of patients. However, none of them has become the leading model yet.

HISTORIC PERSPECTIVE

Coronary artery bypass graft (CABG) has been the standard of care for the management of patients with LMCA disease based on early clinical trials that proved its prognostic benefit in patients assigned to surgery compared to medical therapy. Patients with severe LMCA disease were excluded from most of the early clinical trials and, until recently, no specific trial compared the results of surgery vs PCI as one of its endpoints. Currently, there are randomized clinical trials that have confirmed the utility of the PCI to treat LMCA disease; actually, the American and European clinical guidelines consider it the recommended strategy in certain settings. Approximately, 50% of this type of lesions are revascularized percutaneously in our setting with an annual 5% increase.

ANATOMIC CONSIDERATIONS

Anatomically speaking, the LMCA can be divided into 3 portions: ostial portion, mid-portion, and distal portion; the latter is a bifurcation with an angle that is typically wider compared to other coronary bifurcations (> 70°). It supplies at least 75% of the total coronary flow. The LMCA caliber is often 5 mm ± 0.5 mm and its mean length is 10.5 mm ± 5.3 mm. In up to 30% of the cases it originates a third branch, the ramus intermedium or bisector branch (figure 1).

LMCA atherosclerotic disease is often diffuse. When the bifurcation is affected (in 70% of cases) there is also often presence of plaque at the beginning of the left anterior descending coronary artery (LAD) and left circumflex artery (LCx). At times, the origin of both the LAD and the LCx is independent from the left coronary sinus without LMCA per se (0.41% to 0.67% of cases). In 0.03% of patients, the origin of the LMCA is anomalous describing its trajectory between the aorta and the pulmonary artery, a pattern associated with a high risk of sudden death.

LEFT MAIN CORONARY ARTERY ASSESSMENT

Angiography

The clinical practice guidelines of the European Society of Cardiology establish that the revascularization of the LMCA is indicated for patients with angiographic stenoses > 50% and documented myocardial ischemia. The practical problem here is that coronary angiography has limitations when evaluating LMCA disease with great intra and interobserver variability.

Some ostial lesions can be overestimated due to catheter-induced overlapping and artifact or the presence of an associated spasm. Consequently, distal lesions may be difficult to assess due to the often diffuse affection of the bifurcation and lack of a healthy reference vessel. Damping and/or ventricularization of the pressure curve are indirect data of LMCA disease.

The correct assessment of the severity of LMCA disease is essential given the evidence that functionally nonsignificant lesions have a favorable prognosis without revascularization, and the early graft failure seen in nonsignificant lesions. In this regard, clinical practice guidelines accept the value of diagnostic imaging modalities like intravascular ultrasound (IVUS) and the pressure guidewire to estimate the severity of LMCA disease.

Intracoronary imaging modalities

The IVUS provides information on the structure and anatomy of the LMCA as well as on the presence of plaque, its spread, composition, and classification. Several studies have determined a minimum lumen area (MLA) > 6 mm² as the cut-off value to establish severity. The Spanish multicenter, prospective clinical trial LITRO proved that it was safe to delay the revascularizations of intermediate LMCA lesions with MLAs > 6 mm² with favorable results at the 2-year follow-up. Also, the IVUS helps us determine whether the coronary ostia of LAD and LCx have significant disease. When revascularization is indicated, the IVUS provides information on the right size of the stent and the best strategy should be based on the anatomy and calcium load of the LMCA and proximal LAD/LCx; in lesions due to previous in-stent restenosis, the IVUS characterizes their etiology and the possible damage to the borders of the stent. The IVUS-guided PCI of the LMCA is beneficial compared to the angiography-guided PCI. The need for stent postdilatation and the existence of distal dissection can be assessed too. Also, it can help us determine the need for stent implantation into the lateral branch or exclude the compromise of this branch after implanting a provisional stent. Several parameters have been described for the optimization of IVUS-guided PCIs to treat LMCA disease (figure 2 and figure 3). A large metaanalysis of patients from several Spanish registries confirmed that the use of IVUS is associated with better clinical progression, fewer deaths and infarctions, and particularly stent thrombosis. These findings are especially significant in LMCA distal lesions. Other registries, a few minor clinical trials, and a combined analysis of them all confirm significant clinical benefit from IVUS-guided PCIs performed on the LMCA with fewer deaths, infarctions, and
Pressure wire provides valuable information to stratify the severity of LMCA disease. In order to stop a presumably ostial disease from impacting measurement, pressures need to be equalized and measured using a guide catheter partially «desintubated» from the LMCA. Obtaining hyperemic indices from the LAD and the LCx leads to better overall assessments of the severity of LMCA disease. Also, it secures the decision-making process on the best therapeutic approach. Some authors suggest that IV adenosine is better than intracoronary adenosine to secure the condition of maximum hyperemia.

Another important aspect when assessing the LMCA with the pressure guidewire is the physiological interdependence of the coronary tree that may change the values of fractional flow reserve (FFR).
In particular, the FFR has been reportedly overestimated in the presence of diffuse disease of the LAD and the LCx and underestimated in cases of significant lateral branch disease. Therefore, in the presence of concomitant distal branch disease, measuring the FFR during controlled retrieval can be useful.

Regarding the pathological threshold, it seems that delaying the PCI with FFR values > 0.8 is safe. Although the value of other pressure guidewire indices that don’t require hyperemia like the instantaneous wave-free ratio (iFR) has not been fully assessed in the LMCA, a study proved that using the iFR to delay the revascularization of the LMCA is safe. Currently, the multicenter clinical trial iLITRO (NCT03767621) is being conducted in Spain. This trial will probably shed light on the utility of the iFR and its pathological threshold in the management of LMCA lesions.

Integrating different techniques

Integrating the IVUS and the pressure guidewire in the assessment of the LMCA of angiographically dubious severity is advised as stated by an international consensus document from the European Association of Percutaneous Cardiovascular Interventions.[figure 4]. Therefore, in ambiguous LMCA lesions, MLAs > 6 mm² would be indicative of no revascularization, MLAs < 4.5 mm² to 5 mm² would be indicative of revascularization, and MLAs between 4.5 mm-5 mm to 6 mm² would recommend the use of the FFR/iFR indices before making any decision.

REVASCULARIZATION OF THE LEFT MAIN CORONARY ARTERY

Surgical revascularization

CABG has been the standard of care for patients with LMCA disease since traditional clinical trials confirmed its prognostic benefit in patients randomized to surgery vs medical therapy. The CASS registry reported a 4-year survival rate in 88% of operated patients compared to 63% in non-revascularized patients. Other studies confirmed that the mortality rate dropped to 65% with surgery. This allows a complete revascularization regardless of the characteristics of proximal lesion and technical advances facilitate faster procedures without having to use extracorporeal blood pumps. The main setback is still the non-negligible peri and postoperative morbidity and mortality. Some studies have reported a mortality rate of between 5.5% to 8.5%, a need for ischemia-guided revascularization of 7.1% to 9.4%, and a rate of stroke of 3.1% to 5.1% at the 3-year follow-up.

Percutaneous revascularization

The arrival of stents improved the results of PCI on the LMCA significantly. However, at the beginning, conventional stents fared worse compared to surgery with mortality rates of 14%, a left ventricular ejection fraction (LVEF) > 40% and 78%, and a LVEF < 40% at the 9-month follow-up. With the arrival of drug-eluting stents, the rates of restenosis and adverse events dropped low enough to be able to compare PCI to CABG, with event-free survival rates at the 1-year follow-up of 98% in patients with LVEF < 40%. In patients considered non-eligible for surgery (EuroSCORE > 6 or Parsonnet > 15), the mortality and survival rates without major adverse cardiovascular events were 3.5% and 75.3%, respectively, at the 6-month follow-up. These studies already showed that the PCIs performed on the ostial and mid-portions of the LMCA seemed to have a better prognosis compared to those performed on the distal LMCA or that involved bifurcation. The arrival of new antiproliferative drugs, the development of better devices, and the use of new techniques and strategies to treat bifurcation improved results, efficacy, and the good prognosis of the PCIs performed on the LMCA in experienced centers.

Surgical vs percutaneous revascularization

Six landmark randomized clinical trials have compared percutaneous and surgical strategies [table 1]. The first ones (LE MANS, SYNTAX, Boudriot et al., and PRECOMBAT) were conducted with first-generation drug-eluting stents and reported similar rates of a composite of death, infarction, and stroke for both strategies. The main differences were a higher rate of strokes in the CABG group and a higher rate of new revascularizations after the PCI. The two most recent clinical trials conducted so far, the EXCEL and NOBLE, used second-generation drug-eluting stents and included large cohorts of patients with less complex atherosclerotic disease, which may be indicative of the actual clinical practice. The difference in results obtained by these studies was very controversial; differences were reported in the definition of endpoint and periprocedural infarction as possible determinants. Actually, unlike the EXCEL, the NOBLE trial excluded periprocedural infarction.
from the composite of primary events although its inclusion is recommended by the Academic Research Consortium and is part of the universal definition of myocardial infarction. It has been confirmed that periprocedural infarction is associated with a worse prognosis.\textsuperscript{16} Also, the large difference seen in the rate of stent thrombosis (0.7% in the EXCEL trial vs 3% in the NOBLE trial) is indicative of the possible influence of the different type of stent used in each of these studies.

In general, the results of these studies suggest that when complete revascularization is achieved, both surgery and the PCI achieve similar results for the composite of death, infarction, and stroke at the 5-year follow-up.\textsuperscript{14} However, there is an early benefit for the PCI in terms of periprocedural infarction and stroke that is compensated by the higher risk of infarction at the long-term follow-up. The risk of requiring a new revascularization is evenly higher in patients treated with PCI compared to surgical patients.

Another issue that should be taken into consideration is the correlation between the results of the PCI and the SYNTAX score. The first clinical trials conducted on this topic already suggested that higher scores probably led to a better prognosis with CABG. Some meta-analyses have described that, overall, long-term cardiovascular mortality seems to be directly proportional to the angiographic complexity of LMCA disease. Therefore, patients with low SYNTAX scores had a better prognosis compared to patients with higher scores. Also, patients with high SYNTAX scores showed a non-significant tendency towards a higher 10-year survival rate.

AMI, acute myocardial infarction; CABG, coronary artery bypass graft; ID-TLR, ischemia-driven target lesion revascularization; LMCA, left main coronary artery; LVEF, left ventricular ejection fraction; N/A, not applicable; PCI, percutaneous coronary intervention.
with surgery compared to PCI.\textsuperscript{49,50} One of the main setbacks of this score is that it only includes anatomical variables. Currently, there are other scales including angiographical, clinical, and even functional variables, but their utility as long-term prognostic markers of LMCA disease has not been properly studied yet.\textsuperscript{11}

The current clinical practice guidelines on coronary revascularization\textsuperscript{16} establish the indication for CABG or PCI based on the SYNTAX score (table 2). If complexity is low, the PCIs performed on the LMCA have the same indication as surgery (IA). The PCI is an alternative to surgery in patients with intermediate SYNTAX scores (IIa A) and greater evidence is needed in patients with high SYNTAX scores before clearly recommending PCI.

### Patient selection

The European clinical practice guidelines highlight the importance of the heart team in the decision-making process on which revascularization strategy should be used in stable patients with LMCA disease. This team should include clinical and interventional cardiologists and cardiac surgeons. However, in emergent procedures, surgery is not often a viable option due to the delay involved and the progressive worsening of prognosis in relation to ischemic time. Pappalardo et al.\textsuperscript{52} described in-hospital mortality rates of 21% (basically due to multiorgan failure) in patients with acute myocardial infarction and acute occlusion of the LMCA. However, patients who survived hospitalization and were treated with PCI had a good prognosis with a 1-year survival rate of 89.5%.

In the remaining cases it would be desirable to avoid performing interventional procedures \textit{ad hoc} after the diagnostic procedure. The different revascularization options should be discussed with the clinical cardiologist, the cardiac surgeon, and especially with the patient. The latter should also be objectively informed of the theoretical pros and cons of every technique and the specific results obtained by the treating center making him part of the decision-making process. Other clinical, anatomic and general factors should be taken into consideration too (table 3). Finally, if performing a PCI on the LMCA is considered the best option, the administration of the right premedication, assessment by the heart team, and procedural planning on the technique and materials that will be used are all associated with higher rates of success.

Since most clinical trials have been conducted in centers with coronary care units, performing PCIs on the LMCA in centers without these units has been controversial. However, since there is evidence of the good outcome of PCIs in centers without these units,\textsuperscript{53-55} it is widely accepted that PCIs can be performed on the LMCA in centers safely as long as an experienced medical team is in charge and the necessary technical equipment used. Also, the patient’s informed consent needs to have been collected, and a previous protocol established for urgent transfers to hospitals with coronary care units in the hypothetical case that the patient may require urgent surgery.

**Table 2**

**General factors**

- Similar mortality
- Safe in the short-term
- Early recovery
- Less invasive

**Clinical factors**

- Comorbidities: COPD, elderly, and frail, previous heart surgery, previous stroke, dialysis
- Urgent revascularization

**Anatomical factors**

- Ostial or mid-portion LMCA lesions
- Isolated LMCA lesion
- LMCA lesion and single-vessel disease

**Patients’ preferences and needs**

- CABG, coronary artery bypass graft; COPD, chronic obstructive pulmonary disease; DAPT, dual antiplatelet therapy; LMCA, left main coronary artery; PCI, percutaneous coronary intervention.

### Operators and equipment

The PCIs performed on the LMCA should always be considered high-risk procedures. Actually, the experience of the operators is of paramount importance here. There is evidence that patients treated in high volume centers that perform procedures like this regularly have a better prognosis.\textsuperscript{56}

The equipment should guarantee the proper assessment of the LMCA (IVUS, pressure guidewire). All kinds of materials that may be required to perform the angioplasty and handle all possible complications should be available too. Since it is a high-risk procedure, hemodynamic support devices and resources like the intra-aortic balloon pump and the Impella device (Abiomed, United States) are very important.

### ANGIoplasty of the left main coronary artery

Prior to performing the procedure, it is essential to conduct a comprehensive analysis of the case to decide on the strategy, access route (radial or femoral), caliber of the introducer sheath (due to the presumable need for the double stenting technique, 7-Fr catheters via femoral access or “7 in 6-Fr” catheters via radial access are advised), and type of guide catheter. Although radial access has replaced femoral access in many cases, the PCIs performed on the LMCA are probably a niche where femoral access should be considered since obtaining the least support possible can be key here. Also, this access facilitates the use of larger caliber catheters and the possibility of quick hemodynamic support device implantation.

Damage to the distal LMCA or bifurcation complicates the procedure with more chances of needing 2 stents and a worse prognosis. Other factors associated with worse outcomes and prognoses are calcifications, smaller LMCA diameters, and the presence of non-ostial disease in the LAD or LCx.\textsuperscript{57}

### Wiring and preparation of the lesion

The use of at least 2 angioplasty guidewires (for the 2 main vessels) will be the standard of use in the PCIs performed on the LMCA with notable exceptions like protected LMCA lesions if rotablation...
is required or in some cases of isolated and ostial LMCA disease. Using 2 guidewires slightly changes the bifurcation angle, facilitates access to the lateral branch and maintains flow towards it. Using 2 guidewires also helps find this lateral branch in cases of occlusion. Actually, some authors advocate the use of the bailout technique with balloon when flow is compromised after stent implantation into the main vessel.\textsuperscript{54} Predilatation of the main vessel should be avoided if both vessels have not been protected first due to the high risk of changing and moving the plaque, which could occlude the coronary ostium of a branch complicating further catheterizations.

The use of plaque bulking techniques (rotablation or laser, among other) to change the anatomy and facilitate the angioplasty can be considered. LMCA ostial lesions often consist of abundant calcification and large amounts of elastic muscle fibers, which is associated with a risk of elastic retraction of the lesion both after predilatation and stent implantation. On the other hand, the presence of fibrocalcific plaques can condition the use of cutting balloons as the first step and even rotablation, that has proven beneficial in angioplasties of bifurcated LMCA prior to the implantation of drug-eluting stents.\textsuperscript{55,56} When the lateral branch shows severe ostial or heavily calcified disease or access to it becomes complicated, predilatation with a non-compliant small-caliber balloon is advised.

**Stent selection**

Two different scenarios should be looked into when choosing the right stent: whether only the LMCA or the bifurcation should be treated. Treating the LMCA may be justified only in cases of isolated ostial or mid-portion disease. In this situation, a stent of nominal size should be picked that should reproduce the size of the LMCA as much as possible. Another option would be to implant a stent of a smaller size and overexpand it with a high-pressure balloon of the right dimensions. Several platforms achieve large degrees of expansion without jeopardizing the integrity of its structure.\textsuperscript{51,52} However, there is no clear evidence that stent overexpansion is a safe practice since it is subject to the suboptimal coverage of the intima layer due to metal-to-artery ratio reduction. Also, it can change the polymer or kinetics of the drug-eluting stent.

When the bifurcation should be treated, the stent implanted into the LMCA should cover the proximal portion of 1 of the 2 main vessels. Also, its size should match the proximal diameter of that main vessel. Another important aspect here is having to use the proximal optimization technique (POT) with a non-compliant balloon to adapt the stent proximal caliber to the LMCA. Recrossing towards the lateral branch or using the double stenting technique can be an option too.

Stents implanted into the LMCA are especially prone to proximal deformation because they are in continuous contact with the guide catheter, due to the need for using the POT, and because they scrape against other devices that come through after implantation.\textsuperscript{53} Therefore, the resistance of every stent to longitudinal compression is a factor that should be taken into consideration during stent selection. Other fundamental characteristics that should be looked into when choosing the ideal stent to perform PCIs on the LMCA are the safety profile and precision provided by the stent (figure 5).

**Selection of the bifurcation technique**

**Non-complex bifurcation**

When LMCA disease affects 1 bifurcation branch only or the LCx has a small caliber (< 2.5 mm), the best strategy is the provisional stenting technique with a single stent implanted from the LMCA towards the main vessel. In general, the LAD is the main vessel and only in some cases it would be the LCx. Afterwards, the use of the POT with a non-compliant balloon of the right size is routinely advised.

There are times when it is necessary to fully cover the length of the LMCA. In these cases, it is extremely important to be very precise when implanting the stent to treat the coronary ostium properly and avoid any significant stent protrusions into the aorta.

However, there is still controversy over whether it is necessary to always recross it towards the lateral branch and optimize it with the kissing balloon technique in the bifurcation after using the POT if the provisional stenting technique proves insufficient. The kissing balloon technique should be used with suboptimal final outcomes in the lateral branch, when the main vessel selected is the LCx, and when the future need for a PCI on the lateral branch cannot be discarded.\textsuperscript{4}

**Complex bifurcation**

When disease affects both bifurcation branches significantly, the use of the double stenting technique should be considered. However, since different registries report that the rates of restenosis and new revascularizations are lower with the single stenting technique,\textsuperscript{50,54-56} the early approach in many centers and in most complex bifurcations is often using the provisional stenting technique with the possibility of finishing using the double stenting technique, if necessary. With suboptimal results, the expert committee of the European Bifurcation Group recommends using double T stenting, the T and small protrusion (TAP) or the culotte technique as the bailout strategy after provisional stent implantation.\textsuperscript{67} Once the second stent has been implanted into the lateral branch, individual dilatation in both branches is advised using non-compliant balloons to secure the ostial expansion of the stent of the LAD and the LCx followed by the kissing balloon technique. If it takes over a significant portion of the LMCA, a new proximal dilatation (re-POT) should be performed to optimize the result.

When the double stenting technique is used right away, this selection is often based on different factors: anatomical and angiographic variables, location of the lesion, intracoronary imaging modalities,
In conclusion, there is no doubt that PCIs performed on LMCA lesions crossed their own particular Rubicon a long time ago. *Alea jacta est* (which is Latin for "the die is cast") and, in the future, new randomized clinical trials on surgical or percutaneous revascularization and technical advances in both modalities will favor one over the other. Currently, the SYNTAX score, the possibility of complete revascularization, and the patient’s comorbidities are the main criteria that should guide the selection of percutaneous or surgical revascularization.

Regarding the PCIs performed on LMCA lesions, there are 2 different categories: isolated ostial or mid-portion LMCA lesions (technically easier to treat and with an excellent prognosis), and bifurcation lesions (with a more complex approach).

Optimizing the PCIs performed on the LMCA is essential using intravascular ultrasound and techniques and stents backed by the highest level of evidence in this setting followed by the proper pharmacological cover.

In conclusion, there is no doubt that PCIs performed on LMCA lesions crossed their own particular Rubicon a long time ago. *Alea jacta est* (which is Latin for "the die is cast") and, in the future, new randomized clinical trials on surgical or percutaneous revascularization and technical advances in both modalities will favor one over the other. In the meantime, revascularizations based on every individual patient and in close collaboration with the heart team should guide the routine practice of clinical cardiologists and interventional and cardiac surgeons.

**MEDICAL THERAPY AFTER PERCUTANEOUS CORONARY INTERVENTION AND FOLLOW-UP**

Although angioplasties performed on bifurcations are a predictor of events, currently, there is no evidence available to recommend a specific antiplatelet therapy in angioplasties performed on the LMCA. Therefore, treatment should be administered based on each patient’s clinical presentation and ischemic and hemorrhagic risk profile. However, we should bear in mind that implanting a stent into the LMCA and performing a PCI on a bifurcation, especially when 2 stents are used, are criteria that add more ischemic risk to the profile of these patients.

The reappearance of suggestive symptoms or documented ischemia justifies an invasive approach. The review coronary angiography performed at the 1-year follow-up in patients with angioplasty on the LMCA has a level IIB C indication according to European clinical practice guidelines, and is not justified in all cases. The randomized clinical trial ANGELINE (Angiographic evaluation of left main coronary artery intervention) (NCT04604197) will bring more evidence on the potential advantages of the systematic angiographic review.

**CONCLUSIONS**

The assessment of LMCA lesions is complex, which is why acquiring different angiographic views and using imaging modalities like IVUS or pressure guidewire is advised.

Regarding the PCIIs performed on LMCA lesions, there are 2 different categories: isolated ostial or mid-portion LMCA lesions (technically easier to treat and with an excellent prognosis), and bifurcation lesions (with a more complex approach).

Optimizing the PCIIs performed on the LMCA is essential using intravascular ultrasound and techniques and stents backed by the highest level of evidence in this setting followed by the proper pharmacological cover.

In the meantime, revascularizations based on every individual patient and in close collaboration with the heart team should guide the routine practice of clinical cardiologists and interventional and cardiac surgeons.
