Emergency transcatheter aortic valve implantation in cardiogenic shock: a case report

Implante percutáneo de válvula aórtica emergente en shock cardiogénico: a propósito de un caso

To the Editor,

Transcatheter aortic valve implantation (TAVI) is a therapeutic alternative that has proven safe and effective across different clinical settings. Over the last few years, more and more cases of «emergency TAVI» have been reported. Currently, this term is often used for those implantation procedures performed during admission due to decompensated heart failure although this concept includes very different situations. The therapeutic option to treat cardiogenic shock should be «emergency TAVI», that is, implantation performed within the first 72 hours after admission. This is the case of a patient with severe aortic stenosis who was transferred to our center with signs of cardiogenic shock.

The echocardiogram confirmed the presence of a left ventricular ejection fraction of 10% with moderate mitral regurgitation (video 1 of the supplementary data) and severe aortic stenosis (figure 1A). The levels of arterial lactate upon the patient’s arrival were 3.6 mmol/L. Given the situation of normotensive cardiogenic shock, inotropic treatment with dobutamine [up to 12 mcg/kg/min] was initiated. It improved cardiac index up to 2.2 L/min/m² and brought lactate levels back to normal within the first 8 hours after admission. A computed axial tomography (that same afternoon) and coronary angiography (the next morning, figure 1B) were performed. The screening results obtained were favorable for transcatheter aortic valve implantation:

- Tricuspid aortic valve. Coronary artery calcium score, 2100.
- Aortic annulus: perimeter, 88 mm; area, 556 mm².
- Sinus segment: 35 mm x 33 mm x 33 mm.
- Distance between annulus and left main coronary artery: 11 mm; to right coronary artery, 17 mm.
- Significant lesion to the ostial left anterior descending coronary artery with distal TIMI-grade 3 flow (Thrombolysis in Myocardial Infarction) and no data suggestive of complications. Chronic total coronary occlusion of right coronary artery.
- Calcified femoral accesses without significant lesions and proper caliber.

When multi-organ failure recovered, and hemodynamic data collected with the Swan-Ganz catheter came back to normal, the heart team recommended «emergency TAVI» given the situation of cardiogenic shock, and management of coronary artery disease was deferred and treated in a second surgical act.

The patient was intubated before the procedure. After predilatation with a 25 mm balloon, a 34 mm Evolut PRO valve (Medtronic, United States) was implanted via left femoral artery in the

cusp-overlap view to optimize commissural alignment and minimize damage to the conduction system. Final outcomes were excellent without gradient or residual aortic regurgitation. The patient showed transient left bundle branch block, which is why atrial pacing stress echocardiography was conducted that did not reach the Wenckebach point at 130 beats per minute, which is why the electrocatheter was eventually removed. Left femoral artery was closed with 2 Perclose Proglide sutures as the good results seen on the angiography confirmed [video 2 of the supplementary data]. Hemodynamic improvement was immediate. The patient was progressively weaned off dobutamine and extubated early. Prognostic benefit treatment was optimized, and the cardiac magnetic resonance imaging showed a left ventricular ejection fraction of 28% with viability in the entire myocardium. The patient was discharged 2 weeks after admission for close follow-up, and to plan outpatient coronary revascularization.

This case exemplifies the delicate balance between the time when the cause for the shock was corrected and the hemodynamic stabilization and optimization of organ perfusion was achieved. A recent review and meta-analysis found no differences whatsoever between emergency and elective implantation. However, the rate of acute kidney injury was higher; due to the severity of these patients, the 1-month mortality rate after emergency implantation is twice as high compared to elective implantation [8.8% vs 4.4%]. If only patients with cardiogenic shock are considered, the 1-month mortality rate is higher [11.8% up to 33.3%]. In conclusion, we believe that «emergency TAVIs» is a therapeutic alternative associated with good clinical outcomes.
